A Pilot Ablation Study of Quantum-Layer Placement in Hybrid Networks for Biomedical Tabular Classification

Xiaoming Liu

Abstract

Hybrid quantum-classical architectures are easy to overclaim on small biomedical benchmarks, where strong classical baselines and low statistical power can make minor differences look decisive. We revisit a lightweight teacher-student pipeline with PCA compression, a compact classical student, a 4-qubit parameterized quantum layer, and knowledge distillation (KD) for biomedical tabular classification. We rerun the main Breast Cancer Wisconsin Diagnostic (WDBC) comparison with 10-fold cross-validation, retain the original WDBC ablations, and add companion Pima Diabetes and Heart Statlog benchmarks plus pilot cross-dataset placement checks.

On WDBC, the tail-placement Hybrid-KD model matches but does not reliably outperform the classical student (AUC 0.9926 ± 0.0095 vs. 0.9947 ± 0.0081), and the hybrid cost remains in the hundreds of seconds per fold rather than sub-second. The placement result also needs a narrower interpretation than our original draft: front insertion is fragile in this implementation because direct PCA-to-qubit mapping induces heavy `Tanh` saturation and removes the learnable pre-quantum projection, whereas middle and tail remain viable. Pima and Heart show only modest, statistically uncertain hybrid gains under much higher simulation cost.

We therefore present the study as a pilot ablation of placement and input conditioning, not as definitive evidence that lightweight hybrid models outperform compact classical baselines.

1 Introduction

Quantum machine learning (QML) continues to attract interest as a possible route toward practical learning systems on near-term quantum hardware. In practice, however, large quantum circuits remain hard to optimize and expensive to simulate, especially in data regimes where strong classical baselines are already available [3]. Hybrid quantum-classical (HQC) models therefore remain the most realistic design pattern: a classical front-end performs feature compression, while a small parameterized quantum circuit (PQC) acts as a learnable nonlinear block [4].

Biomedical tabular classification is a useful setting for testing this idea. Such datasets are often small, feature-limited after preprocessing, and measured under strict performance-cost constraints. A compact HQC model may therefore provide insight into how and where a quantum block can be inserted, even if no quantum advantage is expected. At the same time, knowledge distillation (KD) offers a natural mechanism for transferring supervision from a larger classical teacher to a smaller classical or hybrid student [2].

This paper asks three concrete questions on the WDBC benchmark:

1. Does KD help a hybrid quantum-classical student, and how does the KD weight α affect the trade-off between AUC and F1/MCC?

2. Where should the quantum layer be placed inside the student network?
3. Is the hybrid student worth its simulation cost relative to a lightweight classical student, considering both training and inference time?

Our contributions are as follows. First, we revisit the main classical-versus-hybrid comparison on WDBC with a 10-fold robustness check and explicit uncertainty reporting rather than relying only on 5-fold mean±std summaries. Second, we retain the WDBC ablations on placement, PCA dimension, and KD weight α while extending the study with companion Pima Diabetes and Heart Statlog benchmarks. Third, we add pilot cross-dataset placement checks on Heart and Pima to test whether the front/middle/tail pattern is specific to WDBC. Fourth, we provide a circuit diagram, discuss the limited expressibility of the 4-qubit 1-layer ansatz, and explicitly frame the study as a pilot ablation rather than definitive evidence of hybrid superiority.

2 Related Work

2.1 Hybrid Quantum-Classical Classification

Hybrid quantum-classical models couple classical feature extractors with shallow PQCs to keep the quantum component small enough for near-term simulation or deployment [3, 4]. A central design question is where to insert the quantum block: before, within, or after the classical network. Prior work has explored this idea for image, text, and tabular settings, but biomedical tabular benchmarks remain comparatively underused despite their natural low-dimensional structure after feature selection or PCA [5]. Shallow ansatze such as `BasicEntanglerLayers` trade expressibility for trainability, reducing the risk of barren plateaus that plague deeper circuits [6]. Recent work on variational quantum classifiers has demonstrated competitive performance on small tabular benchmarks when paired with careful data encoding and feature compression [12, 13], and quantum kernel methods have shown promise on biomedical classification tasks where classical kernels struggle with structured feature interactions [14, 15].

2.2 Knowledge Distillation for Quantum Models

KD transfers information from a stronger teacher to a smaller student through softened targets and has become a standard compression tool in classical deep learning [2]. The distillation loss interpolates between hard-label cross-entropy and a KL-divergence soft-target term weighted by temperature T and mixing coefficient α. Recent QML work has extended KD to classical-to-quantum and quantum-to-quantum transfer settings, arguing that a stable classical teacher can regularize difficult hybrid optimization [7]. Subsequent studies have shown that KD can improve trainability of variational quantum circuits by smoothing the loss landscape [16] and that quantum-aware distillation strategies outperform naive transfer on noisy intermediate-scale devices [17]. A largely open question is how the information content of teacher soft outputs—measured by their predictive entropy—affects the magnitude of KD benefit, particularly for small biomedical tasks where the teacher may already be near-saturated.

2.3 Biomedical Tabular Classification

Biomedical tabular tasks typically involve limited sample size, moderate class imbalance, and a need for interpretable, compact models. Classical baselines such as gradient-boosted trees and small MLPs are already strong on these benchmarks, raising the bar for any quantum enhancement. PCA-based compression is especially relevant when quantum inputs must be bounded by the number of available qubits [5]. This makes datasets like WDBC, Pima Indians Diabetes, and Heart Statlog suitable benchmarks for controlled HQC experiments: they span a

range of sample sizes, feature dimensions, and task difficulties, enabling cross-dataset analysis of how teacher confidence and KD interact with quantum-layer placement.

3 Method

3.1 Problem Setup

Given a binary biomedical tabular dataset $\mathcal{D} = \{(\mathbf{x}_i, y_i)\}_{i=1}^{N}$ with $y_i \in \{0, 1\}$ and $\mathbf{x}_i \in \mathbb{R}^d$, we aim to learn a compact classifier that keeps predictive quality high while reducing model size and simulation cost.

3.2 Preprocessing

Within each training fold, we apply standard scaling followed by PCA to a target dimension $d' \in \{4, 6, 8\}$. All preprocessing is fit on the training split only and then applied to the validation split to avoid data leakage. The default experiments use $d' = 4$. Although the codebase supports SMOTE-based resampling, all reported results here use no class rebalancing.

3.3 Teacher and Student Models

The teacher is a classical multilayer perceptron with hidden dimensions $[64, 32]$ and dropout 0.2. The classical student uses hidden dimensions $[16, 8]$.

The hybrid student contains three stages:

1. a classical projection network,
2. a quantum layer with 4 qubits and 1 variational layer,
3. a classical output head producing a binary logit.

We evaluate three insertion positions for the quantum block: front, middle, and tail. In the front variant, the first four PCA components are squashed by `Tanh` and fed directly to the quantum layer, so this setting has no learnable pre-quantum projection. In the middle and tail variants, a classical projection network learns a bounded 4-dimensional representation before angle encoding.

3.4 Quantum Layer and Circuit Design

The quantum block uses PennyLane's `AngleEmbedding` with Y rotations for data encoding, followed by `BasicEntanglerLayers` for variational processing [8]. The circuit for $n = 4$ qubits and $L = 1$ variational layer is structured as follows:

1. **Encoding:** Apply $R_Y(x_i)$ on qubit i for $i \in \{0, 1, 2, 3\}$.
2. **Variational layer:** Apply $R_X(\theta_i)$ on each qubit, then a wrap-around ring of CNOT gates.
3. **Measurement:** Return $\langle Z_i \rangle$ for all i.

A schematic representation using `quantikz` notation is:

The effective circuit depth is 2 (encoding + one entangling block), giving 4 trainable parameters. This is a deliberately shallow ansatz: it is sufficient to introduce nonlinear quantum correlations without incurring excessive simulation cost or barren plateau risk [6].

Expressibility. For a 4-qubit, 1-layer `BasicEntanglerLayers` ansatz, the expressibility—measured as the KL divergence between the distribution of state fidelities and the Haar-random distribution [9]—is relatively low compared to deeper alternating-layered ansatze. This is a deliberate trade-off: higher expressibility circuits improve representational capacity but increase gradient variance and simulation cost. For a near-saturated binary task like WDBC, the shallow ansatz is both practical and sufficient to test placement effects. As discussed later in Section 5.4, the quantum block contributes only four trainable parameters, so any performance differences cannot be attributed to parameter count alone.

3.5 Knowledge Distillation

The student objective combines a hard-label BCE term with a soft-target distillation term:

$$\mathcal{L} = (1-\alpha)\,\mathcal{L}_{\text{hard}} + \alpha T^2 \mathcal{L}_{\text{KD}}, \tag{1}$$

where T is the distillation temperature, $\alpha \in (0,1)$ is the KD weight, and $\mathcal{L}_{\text{KD}}$ is the KL divergence between teacher and student soft outputs scaled by T^2. In the main runs we use $T = 2$ and $\alpha = 0.5$.

3.6 Optimization and Evaluation Protocol

Unless noted otherwise, all models are trained with Adam at learning rate 10^{-3} for 80 epochs. The default batch size is 32. For the hybrid follow-up runs on Pima and Heart we reduce the batch size to 8 to keep statevector simulation practical. We do not perform dataset-specific hyperparameter search; instead, we keep the same optimizer, temperature, and architecture settings across the reported comparisons. Thresholded metrics use a fixed decision threshold of 0.5.

The main WDBC classical-versus-hybrid comparison is re-run with stratified 10-fold cross-validation. The WDBC placement, PCA-dimension, and α ablations retain the original 5-fold protocol to stay comparable with the earlier pilot runs. The companion Pima and Heart benchmark tables use 5-fold cross-validation, while the follow-up placement checks on those two datasets are reported as 3-fold pilot experiments because each placement requires a full hybrid retraining loop. We report mean±std together with 95% confidence intervals and paired t-tests plus Cohen's d_z effect sizes for key AUC comparisons.

Table 1: Dataset statistics.

Property	Value
Samples	569
Raw features	30
PCA dimensions evaluated	4 / 6 / 8
Positive class (malignant)	212 (37.3%)
Negative class (benign)	357 (62.7%)
Missing values	0
Task	Binary classification

Table 2: Main results on WDBC (10-fold CV, PCA $d' = 4$, $\alpha = 0.5$, $T = 2$). Hybrid students use the tail placement selected for the robustness rerun.

Model	AUC	F1	MCC
Teacher (MLP-64-32)	0.9937 ± 0.0090	0.9435 ± 0.0310	0.9127 ± 0.0488
Student-Classic	0.9947 ± 0.0081	0.9405 ± 0.0406	0.9100 ± 0.0598
Student-Classic-KD	0.9941 ± 0.0090	0.9408 ± 0.0372	0.9086 ± 0.0571
Student-Hybrid-NoKD (tail)	0.9859 ± 0.0171	0.9462 ± 0.0434	0.9161 ± 0.0682
Student-Hybrid-KD (tail)	0.9926 ± 0.0095	0.9437 ± 0.0381	0.9157 ± 0.0541

4 Experiments

4.1 Dataset

The Breast Cancer Wisconsin (Diagnostic) dataset [1] contains 569 samples, 30 continuous features, and binary labels with 212 malignant and 357 benign cases. There are no missing values.

4.2 Main Results

Table 2 shows that the classical student remains a very strong baseline on WDBC even under the 10-fold rerun. The tail-placement hybrid models match the classical student on thresholded metrics but do not reliably exceed it on AUC. KD recovers much of the tail model's AUC gap relative to the no-KD tail baseline, yet the gain remains modest. The teacher's soft outputs are still highly confident on WDBC (10-fold validation entropy $\bar{H}_{\text{val}} = 0.099$ bits), which helps explain why KD effects remain limited.

As summarized in Table 3, neither the hybrid-KD tail model nor the classical-KD model yields a conventionally significant AUC gain over the classical student on WDBC. We therefore treat the WDBC results as descriptive pilot evidence rather than definitive pairwise superiority claims.

4.3 Ablation: Quantum Layer Position

The WDBC placement study in Table 4 still reveals a sharp front-versus-bounded gap, but the mechanism needs a narrower interpretation than in the original draft. In the front variant, the model takes only the first four PCA components, applies `Tanh`, and feeds them directly into angle embedding without a learnable pre-quantum projection. On the five WDBC training folds, about 36.5% of these direct front inputs satisfy $|\tanh(x)| > 0.95$ and about 21.3% exceed 0.99, indicating strong saturation before the quantum circuit. Under this implementation, front placement is therefore an input-conditioning failure mode rather than evidence that front insertion is fundamentally impossible.

Table 3: Key paired AUC comparisons with uncertainty estimates. Positive ΔAUC means the second model in the comparison has higher AUC.

Comparison	ΔAUC	95% CI	p	d_z
WDBC: Classic vs. Hybrid-KD (tail)	-0.0021	$[-0.0046, 0.0004]$	0.092	-0.63
WDBC: Hybrid-NoKD (tail) vs. Hybrid-KD (tail)	$+0.0068$	$[-0.0006, 0.0141]$	0.067	0.70
Pima: Hybrid-NoKD vs. Hybrid-KD	$+0.0059$	$[-0.0148, 0.0267]$	0.472	0.40
Heart: Hybrid-NoKD vs. Hybrid-KD	$+0.0121$	$[-0.0170, 0.0411]$	0.312	0.58

Table 4: WDBC placement ablation for the KD hybrid student (5-fold CV, $d' = 4$, $\alpha = 0.5$, $T = 2$).

Position	AUC	F1	MCC	Train (s/fold)	Circuit Depth
Front	0.6721 ± 0.0638	0.0560 ± 0.1120	0.0577 ± 0.1154	226.78 ± 3.95	2
Middle	0.9894 ± 0.0089	0.9510 ± 0.0262	0.9236 ± 0.0420	384.56 ± 35.80	2
Tail	0.9903 ± 0.0073	0.9504 ± 0.0187	0.9240 ± 0.0277	347.34 ± 68.03	2

Middle and tail placement define the viable operating region. On WDBC, tail gives the best AUC/MCC while middle gives the best F1. On the new Heart placement pilot, front collapses again (0.5313 ± 0.0468 AUC), whereas middle and tail remain competitive (0.8923 ± 0.0123 and 0.8757 ± 0.0229 AUC, respectively). The Pima pilot shows the same front-versus-bounded split: front remains weak (0.6019 ± 0.0113 AUC), whereas middle and tail recover to 0.7838 ± 0.0311 and 0.7875 ± 0.0298 AUC. The placement conclusion is thus more specific and more defensible: front insertion is fragile in this implementation, while middle and tail are the two competitive options and their ordering is dataset-dependent.

4.4 Ablation: PCA Dimension, KD Weight, and Temperature

Increasing the PCA dimension from 4 to 6 or 8 improves F1 and MCC substantially; 6 dimensions provides the best balanced operating point, while 8 dimensions maximizes F1/MCC at a small AUC cost. The tail-placement α sweep does not show a monotone trend: $\alpha = 0.3$ gives the best AUC, whereas $\alpha = 0.5$ and $\alpha = 0.7$ produce clearly better F1/MCC and are nearly tied on threshold-based metrics. Temperature $T = 2$ remains preferable overall.

4.5 Cross-Dataset Summary

Table 6 brings the WDBC, Heart, and Pima results into one main-text view, while the appendices retain the full dataset-specific tables and fold-level details. The pattern is qualitative rather than monotone: WDBC has a near-saturated teacher and only a small AUC recovery with essentially flat MCC, Heart has moderate teacher uncertainty and the clearest hybrid gain, and Pima has richer teacher uncertainty but a weaker teacher and therefore a smaller gain than Heart. Across all three datasets, these hybrid gains remain modest relative to the simulation-cost gap and do not overturn the strong classical baseline.

5 Discussion

5.1 Does KD help hybrid students?

KD helps the hybrid student selectively rather than uniformly. As summarized in Tables 3 and 6, WDBC shows at most a suggestive AUC recovery under KD, whereas Heart and Pima show modest but still statistically uncertain gains. The pattern is non-monotonic in teacher entropy and too underpowered to justify a simple "KD always helps hybrid models" claim.

Figure 1: Quantum layer placement on WDBC. Front placement collapses; middle and tail remain competitive.

5.2 Which quantum layer position is best?

The placement ablation supports a narrower and more implementation-aware conclusion than the original title suggested. The front variant is fragile because it combines direct PCA-to-qubit mapping, heavy `Tanh` saturation, and the removal of a learnable pre-quantum projection. Middle and tail placement consistently avoid this failure mode, but no universal winner emerges between them: tail is slightly stronger on WDBC and in Pima AUC, whereas middle is stronger in the Heart pilot and in Pima's thresholded metrics. The actionable lesson is therefore not "placement always dominates," but rather "front placement requires much better input conditioning than this lightweight pipeline currently provides." In short, placement is not a silver bullet; conditioning and projection design are the real levers.

5.3 Is the hybrid student worth the cost?

For all three datasets considered here, the answer is still generally no. In the serial 5-fold runs, classical training remains sub-second per fold, whereas hybrid training requires hundreds of seconds per fold: roughly 276–330 s on WDBC, 214–221 s on Heart, and 607–617 s on Pima. Inference for the hybrid models is likewise two to three orders of magnitude slower than the classical students in statevector simulation. Even when the hybrid models recover some AUC or MCC, those gains are too small and too statistically fragile to offset the simulation-cost gap. The hybrid layer therefore behaves more like a research probe than a cost-effective production choice on these small tabular benchmarks.

5.4 Parameter Efficiency

Table 7 compares trainable parameter counts across all models for PCA $d' = 4$. The middle-placement hybrid student uses only 201 parameters (4 quantum, 197 classical), which is fewer

Table 5: Ablation of PCA dimension, KD weight α, and temperature T for the KD hybrid student. PCA and temperature runs follow the notebook-04 default middle placement; the α sweep is reported separately under the tail placement selected by Table 4.

Setting	Value	AUC	F1	MCC
PCA dim	4	0.9924 ± 0.0088	0.9423 ± 0.0191	0.9103 ± 0.0300
PCA dim	6	0.9926 ± 0.0072	0.9538 ± 0.0175	0.9283 ± 0.0274
PCA dim	8	0.9888 ± 0.0108	0.9668 ± 0.0119	0.9488 ± 0.0178
α (tail)	0.3	0.9920 ± 0.0082	0.9358 ± 0.0303	0.9013 ± 0.0440
α (tail)	0.5	0.9918 ± 0.0067	0.9510 ± 0.0186	0.9231 ± 0.0302
α (tail)	0.7	0.9903 ± 0.0071	0.9504 ± 0.0187	0.9240 ± 0.0277
T	2	0.9929 ± 0.0073	0.9442 ± 0.0228	0.9127 ± 0.0367
T	4	0.9932 ± 0.0060	0.9331 ± 0.0390	0.9004 ± 0.0528

Figure 2: PCA dimension on WDBC. Larger compressed inputs improve F1/MCC, with 6 dimensions offering the best balance.

than the classical student's 225, yet achieves comparable AUC and F1 on WDBC. The front-placement variant is the most compact (53 parameters), but it also removes the learnable pre-quantum projection used by the middle and tail variants. The tail-placement hybrid (305 parameters) trades a modest parameter increase for the strongest WDBC AUC/MCC operating point. The parameter table is therefore useful for transparency, but it also shows why the placement ablation should not be interpreted as a pure "same-capacity, different-location" comparison.

5.5 Limitations

This work should be read as a pilot ablation study, not as definitive evidence for hybrid quantum advantage on biomedical tabular tasks. Even after the 10-fold WDBC rerun, several paired confidence intervals still overlap zero, and the companion Pima/Heart placement checks are only 3-fold pilot experiments. The datasets themselves remain small (WDBC 569, Heart 270, Pima 768), so broader generalization is still limited. On the modeling side, we evaluate only one

Figure 3: KD weight under tail placement. Lower α slightly improves AUC, while $\alpha = 0.5$–0.7 yields better F1/MCC.

Table 6: Cross-dataset summary of teacher entropy and KD benefit for the hybrid student. Δ values are computed as Hybrid-KD minus Hybrid-NoKD. Teacher entropy $\bar{H}$ is the mean per-sample soft-output entropy averaged over validation folds. Full per-dataset tables are reported in Appendices B and C.

Dataset	Teacher AUC	$\bar{H}_{\text{val}}$ (bits)	ΔAUC	ΔMCC
WDBC (N=569)	0.994	0.099	+0.007	−0.000
Heart (N=270)	0.889	0.470	+0.012	+0.022
Pima (N=768)	0.782	0.707	+0.006	+0.017

4-qubit, 1-layer `BasicEntanglerLayers` ansatz; we do not report a deeper-circuit comparison, learning-curve analysis, or an exhaustive hyperparameter search. On the systems side, all experiments use noiseless simulation on PennyLane's `default.qubit` [8]; we do not evaluate finite-shot sampling, hardware noise, calibration drift, queueing latency, or real NISQ execution. Future work should extend the same protocol to broader datasets, deeper circuits, and noise-aware simulation or hardware settings.

6 Conclusion

We presented a pilot ablation study of a lightweight hybrid quantum-classical pipeline for biomedical tabular classification. The updated WDBC 10-fold results do not support a definitive hybrid advantage over a compact classical baseline: the best hybrid variant remains statistically indistinguishable from the classical student on the primary AUC comparison. KD can recover some AUC for the hybrid model, especially away from the near-saturated WDBC regime, but the effect remains small and statistically uncertain across WDBC, Pima, and Heart.

The placement result also requires a narrower interpretation than the original title implied. In this implementation, front placement is fragile because it relies on a direct, heavily saturated PCA-to-qubit mapping with no learnable pre-quantum projection. Middle and tail placement

Table 7: Trainable parameter counts by model ($d' = 4$, n_{qubits}=4, L=1). "Classical" and "Quantum" columns separate parameter types.

Model	Classical	Quantum	Total
Teacher (MLP-64-32)	2 433	—	2 433
Student-Classic [16,8]	225	—	225
Student-Hybrid (front)	49	4	53
Student-Hybrid (middle)	197	4	201
Student-Hybrid (tail)	301	4	305

define the viable region, but their ordering is dataset-dependent rather than universal. The broader practical conclusion is therefore conservative: strong classical baselines remain hard to beat on small biomedical tabular benchmarks, and the hybrid simulation cost stays far above the classical alternatives.

Future work should expand to additional datasets, evaluate noise-aware and shot-based settings, and test whether the same placement and KD dynamics persist under deeper or more expressive ansatz families.

A Teacher Soft-Output Entropy Analysis

To contextualize the limited KD benefit, we analyze the entropy of the teacher's soft predictions over the training folds. For a binary classifier, the per-sample soft entropy is

$$H(p) = -p \log_2 p - (1-p) \log_2 (1-p), \tag{2}$$

where $p = \sigma(z_{\text{teacher}})$ is the teacher's predicted probability. High-confidence predictions ($p \approx 0$ or $p \approx 1$) yield $H \approx 0$, leaving no additional information beyond the hard label.

Across all 10 folds and training samples, the teacher's mean soft-output entropy is $\bar{H}_{\text{train}} = 0.0990$ bits (std. 0.2172), while the validation-fold mean is $\bar{H}_{\text{val}} = 0.0992$ bits (std. 0.2169). The fraction of high-confidence predictions satisfying $|p - 0.5| > 0.45$ is 89.7% on training samples and 89.3% on validation samples. This confirms that the teacher is highly confident on most samples, and its soft targets provide only limited additional signal relative to one-hot labels. This helps explain why KD offers limited benefit to the classical student and why larger α (more soft-target weight) can degrade hybrid student F1/MCC.

B Pima Diabetes Benchmark Details

Section 4.5 gives the main-text synthesis; this appendix keeps the full Pima table and supporting details for reproducibility. To test whether the WDBC observations transfer to a less saturated biomedical task, we ran the same 5-fold protocol on the Pima Indians Diabetes dataset [10] (768 samples, 8 raw features, positive rate 34.9%). We used PCA $d' = 4$, $T = 2$, and the tail placement selected from the WDBC placement study for the companion hybrid runs.

The Pima example paints a different KD picture from WDBC. The teacher's mean soft-output entropy is 0.704 bits on training folds and 0.707 bits on validation folds, with only about 14% of predictions satisfying $|p - 0.5| > 0.45$. This indicates substantially richer soft targets than on WDBC. Correspondingly, the KD hybrid achieves the best AUC and MCC on Pima, while the non-distilled hybrid retains the best F1. Even so, the practical conclusion remains

Table 8: Pima Diabetes main results (5-fold CV, PCA $d' = 4$). p-values from paired t-test vs. Student-Classic (best classical baseline). None are significant at α=0.05.

Model	AUC	F1	MCC	Train (s/fold)	p_{AUC}
Teacher (MLP-64-32)	0.7817 ± 0.0336	0.5706 ± 0.0641	0.3671 ± 0.0817	0.39 ± 0.02	—
Student-Classic	0.7816 ± 0.0290	0.5752 ± 0.0821	0.3774 ± 0.0983	0.32 ± 0.01	—
Student-Classic-KD	0.7781 ± 0.0346	0.5701 ± 0.0721	0.3665 ± 0.0914	0.60 ± 0.02	0.386
Student-Hybrid-NoKD	0.7793 ± 0.0286	0.5941 ± 0.0653	0.3690 ± 0.0866	606.69 ± 100.33	0.683
Student-Hybrid-KD	0.7852 ± 0.0334	0.5800 ± 0.0700	0.3861 ± 0.0908	617.33 ± 14.21	0.422

Table 9: Heart Statlog main results (5-fold CV, PCA $d' = 4$). p-values from paired t-test vs. Student-Classic. None are significant at α=0.05.

Model	AUC	F1	MCC	Train (s/fold)	p_{AUC}
Teacher (MLP-64-32)	0.8894 ± 0.0543	0.7932 ± 0.0774	0.6266 ± 0.1415	0.15 ± 0.02	—
Student-Classic	0.8878 ± 0.0552	0.8070 ± 0.0706	0.6643 ± 0.1208	0.12 ± 0.00	—
Student-Classic-KD	0.8892 ± 0.0470	0.8031 ± 0.0727	0.6547 ± 0.1205	0.22 ± 0.00	0.891
Student-Hybrid-NoKD	0.8736 ± 0.0704	0.7841 ± 0.0860	0.6116 ± 0.1595	221.48 ± 4.68	0.204
Student-Hybrid-KD	0.8857 ± 0.0533	0.7968 ± 0.0760	0.6340 ± 0.1392	214.08 ± 9.04	0.827

similar: the hybrid models are roughly three orders of magnitude slower to train than the classical baselines, so the metric gains are modest relative to simulation cost. We therefore view Pima as supportive evidence that KD can matter more when teacher entropy is higher, but not yet enough to overturn the overall cost-benefit assessment of lightweight classical models.

C Heart Statlog Benchmark Details

Section 4.5 gives the main-text synthesis; this appendix keeps the full Heart table and supporting details for reproducibility. To add a second companion biomedical benchmark, we ran the same 5-fold protocol on the Heart Statlog dataset [11] (270 samples, 13 raw features, positive rate 44.4%). As in the Pima benchmark, we used PCA $d' = 4$, $T = 2$, and the tail placement selected from the WDBC placement study for the companion hybrid runs.

Heart Statlog lands between WDBC and Pima in teacher uncertainty. The teacher's mean soft-output entropy is 0.471 bits on training folds and 0.470 bits on validation folds, with high-confidence fractions of 38.1% and 36.3%, respectively. Compared with the non-distilled hybrid, the KD hybrid improves AUC from 0.8736 to 0.8857, MCC from 0.6116 to 0.6340, and slightly reduces training time, but it still does not surpass the classical student on thresholded metrics. The Heart example therefore supports a narrower version of the Pima conclusion: richer teacher uncertainty can make KD more useful for the hybrid model, yet the overall cost-benefit picture still favors lightweight classical baselines.
